Recent advances in nonlinear coherent microscopy, such as second-\(^2\)3 and third-harmonic generation microscopy,\(^4,5\) and coherent anti-Stokes Raman scattering (CARS) microscopy\(^6-9\) have attracted much interest. Among coherent microscopies, CARS provides vibrational information intrinsic to and characteristic of chemical species. CARS is a third-order nonlinear optical process involving three laser frequencies at \(\omega_a\), \(\omega_b\), and \(\omega_c\), respectively, which interact with the sample and generate an anti-Stokes field at a frequency \(\omega_{AS} = \omega_a + \omega_b - \omega_c\) that is higher than the excitation frequencies. Therefore, CARS can be detected in the presence of one-photon induced fluorescence. The anti-Stokes signal is resonantly enhanced when the Raman shift, \(\omega_a - \omega_c\), coincides with the frequency of a Raman-active molecular vibration, which provides the intrinsic vibrational contrast mechanism.\(^10\) Vibrational imaging based on CARS has been previously demonstrated to be more sensitive than infrared and confocal Raman microscopy techniques,\(^6\) and has three-dimensional sectioning capability and deep penetration depth, similar to other nonlinear microscopy. Since the molecules remain in the electronic ground state, photobleaching and damage to delicate biological samples is minimized. However, CARS detection is not background free. Electronic contributions to the third-order susceptibility from the sample and solvent cause a nonresonant background signal, which provides no vibrational contrast. In addition, the solvent water has strong resonant signals of broad spectral width. Both background signals often overwhelm the CARS signal from small scatterers, and limit the sensitivity. Recently, we have reported significant advances in the sensitivity and spectral resolution of CARS microscopy and its application to the imaging of live unstained cells.\(^7-9\)

Here we use time-resolved CARS (T-CARS)\(^11\) to record the Raman free induction decay (RFID) of molecular vibrations. This not only provides spectroscopic information in the time domain, but also an alternative approach to separate the nonresonant contribution of RFID, which is instanta-
The T-CARS experiment probes the correlation function of the linear polarizability response, \( \alpha(t_2) \), of the sample, which in the case of parallel polarization of the three incident and the anti-Stokes fields takes the following form:\(^{15-17}\)

\[
\alpha(t_2, \Theta, \Phi, \Psi) = A_m \delta(t_2) + \sum_i A_i^\text{miso} \exp(-200i\pi c \tilde{\nu}_i t_2) \\
\times \left[ \left( \rho_i^{-1} - \frac{4}{3} \right) \exp(-t_2/T_{2i}) \right. \\
+ \left. \frac{4}{3} \exp[-t_2(T_{2i}^{-1} + T_{or,i}^{-1})] \right].
\]

Here, the delta function (scaled by \( A_m \)) represents the nonresonant (electronic) response of the system while the \( l \) Raman-active vibrational modes are modeled as damped exponentials of amplitude \( A_i^\text{miso} \), center wavenumber \( \tilde{\nu}_i = 10^{-2} \omega_i/2\pi c \) (in cm\(^{-1} \)), vibrational dephasing time \( T_{2i} \), rotational correlation time \( T_{or,i} \), and depolarization ratio \( \rho_i \).

These parameters can be independently obtained by recording the corresponding spontaneous polarization-controlled Raman spectra of the sample, \( \tilde{\alpha}(\tilde{\nu}) \) and \( \tilde{\alpha}^\perp(\tilde{\nu}) \), by computing their isotropic and anisotropic components, \( \tilde{\alpha}^\text{iso}(\tilde{\nu}) = \tilde{\alpha}(\tilde{\nu}) - \frac{2}{3} \tilde{\alpha}^\perp(\tilde{\nu}) \) and \( \tilde{\alpha}^\text{ani}(\tilde{\nu}) = \tilde{\alpha}^\perp(\tilde{\nu}) \), and by their subsequent decomposition into \( l \) isotropic and anisotropic Lorentzian Raman line profiles with \( \tilde{\nu}_1^\text{iso} = 10^{-2}/\pi c T_{21} \) and \( \tilde{\nu}_1^\text{ani} = (T_{21}^{-1} + T_{or,1}^{-1})/100\pi c T_{21} \). The instrumental response is then the full width of half maximum \([\text{FWHM}]\) of the \( [W_{11}] \) values, respectively.

Numerical simulation of the T-CARS measurement is carried out using Eqs. (1)–(3). The only parameter that is varied is \( A_m \). The time-dependent field envelopes of the incident laser pulses are assumed to be Gaussians, \( E_m(t) = \exp(-2\ln 2/\Delta_m^2) \). The FWHM of the laser pulses, \( \Delta_m \), the laser pulse center wavenumbers, \( \tilde{\nu}_m \), and the spontaneous polarization Raman spectrum of the sample are obtained from independent experiments.

The experimental layout of the RFID microscope is schematically depicted in Fig. 1. A regeneratively amplified Ti:Sapphire laser system that pumps an optical parametric amplifier (OPA) [RegA 9000/OPA, 9400, Coherent Inc.] at a repetition rate of 250 kHz was used to provide synchronized femtosecond pulse trains at three different wavelengths that are given by the fundamental (\( \lambda_1 \)) of the Ti:Sapphire, the signal (\( \lambda_2 \)), and the idler (\( \lambda_3 \)) of the OPA. The different frequencies of the probe and pump beams avoids the interference between the two beams in the colinear geometry. Before being focused, all fields were independently expanded to a beam diameter that matches the back aperture of the objective (Nikon Plan Apo oil, \( 60 \times NA = 1.4 \)) linearly polarized along the x axis, collinearly overlapped, and coupled into an inverted optical microscope (Nikon TE 300). The FWHM values of the laser pulses were \( \Delta_1 = 185 \) fs, \( \Delta_2 = 85 \) fs, and \( \Delta_3 = 115 \) fs as obtained by intensity autocorrelation measurements, with corresponding transform limited spectral band widths of 80, 173, and 128 cm\(^{-1} \), respectively. Two variable optical delay lines were used to control the temporal overlap and delay between the different pulse trains. The anti-Stokes signal was parfocally collected with an identical objective lens in the forward direction, spectrally isolated using interference band pass and holographic notch filters, passed through an analyzing polarizer, and detected by an avalanche photodiode (SPCM-AQR15, EG&G Canada). Images were collected by raster scanning the sample, respective to the fixed laser beams.

To demonstrate the ability of the T-CARS microscope to record RFID, measurements on neat benzaldehyde have been performed. Figure 2(a) displays the parallel and perpendicular polarized spontaneous Raman spectrum with respect to the linear polarized incident field, which was taken with a commercial confocal Raman microscope (LabRam, Dilor). The Raman bands at 1585 and 1598 cm\(^{-1} \) are assigned to the two quadratic stretch components of C=\( \equiv \)C bonds in the benzene ring, whereas the 1700 cm\(^{-1} \) band reflects the nonconjugated C=O stretch vibration.\(^{18} \) Their depolarization ratios amount to 0.43, 0.53 and 0.33, respectively. Figure 2(b) displays the RFID measurement of benzaldehyde when tuned to a Raman shift center at 1636 cm\(^{-1} \), with average powers of each -50 \( \mu \)W.

FIG. 2. Information content of RFID measurements demonstrated for neat benzaldehyde. (a) Parallel \( [\tilde{\alpha}(\tilde{\nu}) \), solid line] and perpendicular \( [\tilde{\alpha}^\perp(\tilde{\nu}) \), dashed line] components of the spontaneous Raman spectrum with respect to the linear polarized orientation of the incident field; (b) Measured (circles) and simulated (line) RFID decay curves. The instrumental response function measured solely from the nonresonant coherent radiation originating from the glass substrate is also shown (squares). Insert: Fourier transform of the oscillatory contributions to the measured RFID. (\( \lambda_1 = \lambda_3 = 800.0 \) nm, \( \lambda_2 = 920.5 \) nm, \( \lambda_2 = 715.6 \) nm, corresponding to a Raman shift centered at 1636 cm\(^{-1} \) with average powers of each -50 \( \mu \)W).
torily reproducing the characteristic features of the observed decay curve. The temporal resolution of the T-CARS microscope is given by the instrumental response function (IRF) that has been independently measured by detecting the solely nonresonant coherent radiation originating from the glass substrate. The FWHM of the IRF amounts to 200 fs.

Next, we apply the technique to demonstrate vibrational imaging of a 1-μm diameter polystyrene bead that is embedded in water. First, the spontaneous Raman depolarization spectra were taken, with the parallel spectrum shown in the inset of Fig. 3(a). The spectrum is decomposed into a series of Lorentzian line profiles, which correspond to the aromatic CH stretching modes of the benzene ring at 3035, 3051, and 3061 cm\(^{-1}\). Figure 3(a) reveals the RFID when focused into the bead and tuned to a Raman shift centered at 3054 cm\(^{-1}\), and therefore coherently exciting all the vibrational modes shown in the inset of Fig. 3(a). The measured RFID curve exhibits an initial fast decay of the IRF, followed by a single exponential decay with a time constant of about \(\sim 390\) fs, which is superimposed with a quantum beat that recurs at \(\tau = 1280\) fs. The fastest feature in the time domain, the decay constant of 390 fs, corresponds to the broadest feature in the frequency domain, the line width (FWHM = 15.4 cm\(^{-1}\)) of the 3035 cm\(^{-1}\) resonance, which gives \(T_2/2 = 345\) fs and appears to be the dominant contribution to the observed RFID curve. The beating of the 3035 cm\(^{-1}\) mode with the 3061 cm\(^{-1}\) mode with a difference frequency of 26 cm\(^{-1}\) accounts for the observed quantum beat period of \(\sim 1280\) fs. More quantitatively, the numerical simulation [Fig. 3(a)] satisfactorily reproduces the experimental data.

Repeating this experiment in bulk water results in a decay curve that solely resembles the IRF. This indicates that the observed signal arises purely from the nonresonant and/or spectrally very broad resonance contributions of water in the 3000–3100 cm\(^{-1}\) range. Figure 3(b) displays ultrafast vibrational images of a polystyrene bead at zero-time delay and at \(\tau = 484\) fs. Comparison of the two images clearly reveals that the time-delayed detection is capable of completely removing the nonresonant background contributions. As such, the solvent background signal is suppressed by a factor of \(\sim 570\), with the remaining background signal in the time-delayed image being limited by the dark count level of the detection system only. In contrast, the maximum signal from the polystyrene bead at time zero is reduced by only a factor of 50. Consequently, the maximum signal from the polystyrene bead at time zero is reduced by only a factor of 50. Consequently, the signal-to-background ratio, \(S/B\), increases from \(S/B(\tau = 0) \approx 3\) to \(S/B(\tau = 484\) fs) \(\approx 35\). In this way, the vibrational contrast in the time-delayed image arises exclusively from the Raman-resonant modes. The lack of interference with any nonresonant signal allows one to quantitatively relate the recorded image pixel intensity to the squared concentration of the vibrational modes within the sample.

In conclusion, the T-CARS microscope is capable of completely removing nonresonant background signal from the sample and the solvent, and thus significantly increases the detection sensitivity of coherent Raman microscopy. Time-domain experiments on vibrational imaging are complimentary to their analogous frequency domain experiments of chemical and biological systems.

The authors thank Professor R. M. Hochstrasser for stimulating discussions, Dr. E. J. Sanchez and Dr. J. X. Cheng for technical assistance with the data acquisition software. This work is supported by a NIH grant (GM62536-01) and a Harvard start-up fund. One of the authors (A.V.) acknowledges support from the Deutsche Forschungsgemeinschaft.
